The Acute Effects of Static and Dynamic Stretching Exercises on Dynamic Balance Performance

Statik ve Dinamik Germe Egzersizlerinin Dinamik Denge Üzerine Akut Etkisi

ABSTRACT

Objective: The main purpose of this study was to investigate the acute effects of static and dynamic stretching exercises on dynamic balance.

Materials and Methods: Sixty-seven recreational athletes (33 males aged 20.5 ± 2.3 yrs and 34 females aged 21.4 ± 3.0 yrs) were tested in three different protocols including the control condition, static stretching, and dynamic stretching exercises on three separate days, 48-72 h apart. Before and after each protocol, double limb dynamic balance was tested on an isokinetic balance system. Each protocol involved warm-up for 5 min using the bicycle ergometer at 50-60 rpm and 70 W. Stretching exercises were applied bilaterally on four different lower extremity muscle groups. For the control condition, after warm-up, subjects rested for 12 min and 45 s. The time period between the two dynamic balance measurements was equal for each protocol.

Results: All three protocols positively affected dynamic balance performance (p<0.01). There was no significant difference between effects of protocols on dynamic balance (p>0.05).

Conclusions: Static stretching after warm-up, dynamic stretching after warm-up, and warm-up alone have positive effect on dynamic balance. Static or dynamic stretching after warm-up do not potentiate positive effect of warm-up alone on dynamic balance.

Keywords: Dynamic balance, static stretching, dynamic stretching, warm-up

ÖZ

Amaq: Bu çalışmanın temel amacı statik ve dinamik germe egzersizlerinin dinamik denge üzerindeki akut etkilerini araştırmaktı.

Gereç ve Yöntemler: Altınay yedi rekreasyonel sporcu (20.5 ± 2.3 yaşarda 33 erkek ve 21.4 ± 3.0 yaşında 34 kadın), 48-72 saat arayla üç farklı gününde; kontrol grubu, statik germe ve dinamik germe egzersizleri olmak üzere üç farklı egzersiz protokolü ile test edildi. Her egzersiz protokolü öncesi ve sonrasında, izokinetik denge testi kullanılarak çift ayak dinamik denge ölçüldü. Her protokollenin, isına 50-60 rpm ile 70 W'da 5 dk süreyle bisiklet ergometresi kullanıldıkları. Germe egzersizleri, bilateral olarak dört farklı ekstremitenin kas grubuna uygulandı. Kontrol grubu, isına sonrasında deneklere 12 dk 45 s dinlenme süresi verildi. İki dinamik denge ölçümü arasındaki süre, her protokol için eşit olarak şekilde ayarlandı.

Bulgular: Egzersiz protokollerinin üçü de dinamik denge performansını olumlu yönde etkiledi (p<0.01). Egzersiz protokollerinin dinamik denge üzerindeki olumlu etkileri arasında fark bulunmadı (p>0.05).
INTRODUCTION

Although it is generally believed that stretching exercises improve sports performance, it has been argued lately that different stretching exercise protocols prior to sports activity may have different effects on performance (1).

Recent scientific studies were designed to investigate the acute effects of stretching exercises, especially dynamic and static type stretching exercises, on components of performance. There are many studies showing that static stretching has negative impact on sports performance (2-5). However, studies using static stretching lasting shorter than 60 s report no negative effect on athletic performance (4,6-11). Few studies have argued that static stretching exercises have positive effect on performance (8,12-14). Unlike static stretching exercises, the effect of dynamic stretching exercises on athletic performance is reported to be positive in many studies (3,5,10-12,15). Studies reporting negative (6,14) or no effect (16) are limited. Two recent reviews (1,17) stated that the duration of stretching can affect the influence of stretching on athletic performance parameters.

Previous studies about stretching and balance primarily investigated the effects of static stretching on balance and reached arguable results, while just a few investigated the effects of dynamic stretching (6,18,19), and only a single study (6) investigated the role of gender.

In the light of the above, this study was designed to address whether static or dynamic stretching exercises should be preferred prior to sports activity. On this point, we focused on balance. The importance of balance ability in injury prevention is well known, and was studied extensively. However balance ability’s effect on athletic performance is less clear (20).

Most of the research investigating the effects of stretching on balance studied dynamic balance (6,7,9,12,13,18) and few studied static balance (2,19,21). Dynamic balance in daily activities and sports activities is necessary for optimum performance (22). Also, poor dynamic balance is an important factor that may increase the risk of injury in athletic participation (23). Therefore, the main purpose of this study was to investigate the acute effects of both static and dynamic stretching exercises on dynamic balance.

MATERIALS and METHODS

Experimental Approach

A self-controlled randomized prospective study design was used to evaluate the acute effects of static and dynamic stretching exercise on dynamic balance performance. Testing consisted of three protocols. The sequence of the three different exercise protocols including static stretching, dynamic stretching, and warm-up alone as a control, was randomly assigned to avoid potential biasing effects. Before and after each exercise protocol, dynamic balance was tested by using an isokinetic balance system.

Subjects

A total of 73 (34 male, 39 female) recreational athletes volunteered to take part in this study. Subjects were players of badminton (n=22: 13 male, nine female), basketball (n=23: nine male, 14 female), and tennis (n=28: 12 male, 16 female), with similar characteristics. Detailed training levels and medical histories of all the subjects were established, and physical exams were completed. Inclusion criteria were: to be 18-30 years of age, to train once or twice a week with a trainer for at least two months. Exclusion criteria were: to have a vestibular, visual, neurological, or musculo-
skeletal problem that can affect balance; to train more than twice a week, musculoskeletal injury in the last six months, using medication that can impair balance.

Two subjects did not complete all protocols, three subjects had leg length discrepancy, and one subject had a muscle injury while playing basketball during the study. After exclusion of six subjects (a male, five females) a total of 67 (33 males, 34 females) subjects were included in the study. Characteristics of subjects are given in Table 1.

The study design was reviewed for ethics and approved by the Ege University Human Investigations Ethic Committee. Participants were informed about potential risks and benefits of participation in the study. No injuries occurred during the testing sessions.

Procedures

Subjects were tested on three different days, 48-72 hours apart. They were asked not to use alcohol and to avoid excessive physical activity for 24 h before testing sessions. Each testing day started with double limb dynamic balance measurement on an isokinetic balance system, which is followed by warm-up, intervention and double limb dynamic balance measurement, respectively. Subjects warmed up for 5 min on a bicycle ergometer at 50-60 rpm and 70 W. Intervention was static stretching protocol, dynamic stretching protocole or rest (sitting on a chair). All interventions lasted 12 min and 45 s.

Stretching protocols

Stretching exercises were applied bilaterally to four different lower extremity muscle groups: knee extensors (quadriceps), knee flexors (hamstring), ankle plantar flexors (gastrocnemius-soleus) and ankle dorsiflexors (tibialis anterior).

Static Stretching Protocol: All static stretches were active and were held at the point of mild discomfort without pain (Figure 1). Each static stretch was repeated three times for 15 s, with a 15 s rest between each stretch repetition and was repeated on the opposite limb. For the plantar flexors, the 15 s stretching was split into two, half for gastrocnemius and half for soleus, beginning with the gastrocnemius.
Quadriceps and hamstring stretching exercises were performed at standing position as described by Şekir et al. (15).

Ankle plantar flexor muscles: In standing position, the subject leans into a solid surface. Foot of the side to be stretched is placed posterior to the other foot while feet are in neutral position, and the subject facing straight to solid surface. The subject leans forward till feeling a mild discomfort in the gastrocnemius muscle while the stretch side knee is straight, and heel is on the ground.
After keeping this position for 7.5 s, the subject moved stretch side foot forward while flexing the same side knee till feeling discomfort in the soleus muscle, and kept this position for another 7.5 s.

Ankle dorsiflexor muscles: In sitting position, subjects lifted the extremity of the side to be stretched and placed foot of the lifted extremity on the opposite side’s knee. While the foot is in neutral position, the subject pulled the anterior part of the foot till feeling a discomfort in tibialis anterior muscle without pain. Pull maneuver was performed carefully to plantar flex the ankle without eversion and inversion (Figure 1).

**Dynamic Stretching Protocol**: Subjects voluntarily contracted the antagonist of the target muscle in standing upright position and flexed or extended the joints involved once every 2 s so that the target muscle is stretched (Figure 2). Dynamic stretching in each muscle group was repeated for two sets 15 times (first five times slowly and then the next 10 times as quickly and powerfully as possible, without bouncing). Every dynamic stretching set resumed 30 s, applying 15 s rest between each stretch repetition.

The order of target muscle and resting periods was the same as those in static stretching, and overall stretching time was the same (11'45") for both dynamic and static stretching protocols.

**Balance protocol**

An isokinetic balance system device (PK-252, Tecnobody, Italy) was used, and the "Equilibrium Management Test" program which is reported to be reliable (24) was selected for dynamic balance measurements (Figure 3). This program gives the Total Stability Index (TSI), which is the average index, degree of tilt in all directions horizontally from the center of the platform, during the measurement of dynamic balance. According to Testerman and Vander (25), TSI is the most important indicator revealing a person’s ability to balance the platform. Low TSI values indicate better balance.

In the "Equilibrium Management Test" program, one of the factors that needs to be set in terms of standardization is the "Force Absorber" system. This system determines the freedom of the platform through four pistons placed beneath the platform. Six different resistance options are available as 1-5-10-20-30-40, from most free to most stable. In a similar study investigating dynamic balance of recreational athletes designed by Costa et al. (12), where the resistance of the piston ranged from one to eight, and the third resistor selected. As this study is carried out on recreational athletes, the appropriate piston resistance was selected as 10.

Placing the feet on the center of the platform is very important for balance measurement, as the reference points that the feet are placed on can alter balance score (26). For this reason, prior to the first dynamic balance measurement, subjects were asked to identify the spot where their feet were at equal distances from the center, and
parallel to each other; and to find the position that they felt comfortable and well-balanced.
Thus, the best position of the feet was marked. These positions were marked through reference points on the disc. Individuals’ feet positions were thus at the same reference points during each trial for standardization.

During the test, subjects were asked to try to keep their position as long as possible by standing double-footed and barefoot on a 55 cm platform. Also, they were asked to keep their hands on the side of their legs, with eyes on the monitor. During the dynamic balance test, if subjects lost balance and contacted the device with their arms, they were immediately asked to try to resume the test.

Measurements of dynamic balance were made before and following the protocols applied. Subjects were allowed three practices before each test attempt to minimize learning effects. Each dynamic balance test lasted 30 s.

The subjects were made to rest for one minute after the application of each protocol; thus, the time period between the two dynamic balance measurements, including the warm-up period, lasted a total of 17’45” for each exercise protocol.

The same researcher explained all procedures to all subjects and controlled every stage for correct timing and stretching movements.

Statistical analysis

Statistical results were analyzed using the SPSS program (v15.0). Descriptive statistics, including means and standard deviations were provided for the data. The Shapiro-Wilk test was used for normality analysis. Non-parametric tests were used due to non-normal distribution of data. Mann-Whitney U test was used to examine the differences between genders. The Wilcoxon sum rank test was used to examine effects of interventions on dynamic balance. Friedman test was used to compare effects of different interventions. Covariance analysis was used to adjust TSI scores to stature. Statistical significance was accepted at the level of p<0.05.

RESULTS

The research revealed that all the three warm-up, static, and dynamic stretching protocols positively affect dynamic balance performance (p<0.01) (Table 2), with no significant difference between either genders (p>0.05) or protocols (p>0.05) (Table 3). There was a significant difference in pre-intervention TSI scores between genders (p<0.001). By adjusting pre-intervention TSI scores to height, mean TSI of males became 1.70 ± 0.12 and that of females 1.61 ± 0.12 (p=0.67).

DISCUSSION

For dynamic balance performance in the three exercise protocols; considering women, men, and all subjects, a positive and statistically significant effect was present, with no difference between genders. In addition, the three protocols were not found to be superior to each other statistically. Lipshits et al. (27) found that when balance is perturbed, lower extremity muscles were the first to respond. This description makes clear the role and importance of the lower limbs to maintain balance. Therefore, in the present study, four different stretching exercises for lower extremity muscle group were applied to assess the effect of balance in standing, which plays a role in stabilizing the knee and the ankle. Thus, distinct from all related articles, the tibialis anterior muscle was added to the assessment due to its impact on ankle stability control.

Behm et al. (2) investigated the acute effect of static stretching exercises on double foot static balance performance by testing 16 male college students. Stretching sessions involved a 5 min cycle ergometer warm-up followed by 3x45 s bilateral static stretching of the quadriceps, hamstrings, gastrocnemius and soleus muscles with a 15 s rest period for each muscle group.

They stated that static balance performance is positively affected by solely warm-up exercises, and the effect of static stretching is negative. Using the same stretching protocol, Costa et al. (12), with the participation of 28 female recreational athletes, investigated the acute effects of different durations of static stretching exercises on double foot dynamic balance performance. The research included warm-up exercises as control, 3x15” and 3x45” static stretching protocols, and concluded that 15” static stretching had positive effects, whereas 45” static stretching or solely warm-up exercises had no effect on dynamic balance performance.

A study by Handrakis et al. (13) investigated the effects of static stretching on balance and tested Soo Bahk Doo (Korean traditional martial arts) athletes consisting of six men and four women 40-60 years of age. Two protocols were applied to all subjects, involving single foot dynamic balance measurement following either 10 min rest or 3x30” static stretching to the lower extremity muscle groups for a total of 10 min. They reported that 30” lasting static stretching exercises had a statistically greater impact on dynamic balance performance. In contrast to this study, Lewis et al. (7) reported that static stretching of lower extremity muscles (3x45”) had no effect on dynamic balance. It should be noted that study designs in these two studies are different from those of Costa et al. (12), Behm et al. (2), and Kim et al. (9), as they only compared static stretching with resting and did not assess the acute effects of stretching, which can be done by comparing pre- and post-balance test results.

Above mentioned studies (2,9,12) are similar to ours in that balance was measured before and after the stretching protocol; therefore, concerning the acute effect of static stretching on dynamic balance, they should be preferred in comparing results. Thus, the effect of static stretching on dynamic balance performance was found to be compatible with the 15” static stretching protocol.
findings of Costa et al. (12). Studies investigating longer static stretching times reported no benefits on balance. Kim et al. (9) stated that static stretching (2x45") has no effect on dynamic balance and Behm et al. (2) reported that static stretching (3x45") negatively affects static balance.

Ghaffarinejad et al. (28) found that 30" static stretching has beneficial effects on joint position sense and emphasized that it resulted from the increase in proprioceptive feedback. Costa et al. (12) commented that this improvement in proprioception could be the mechanism that is responsible for the positive effects on balance. Mechanisms underlying the effect of stretching on balance are not fully understood. More studies should focus on these mechanisms.

To our knowledge, there are only three studies in current literature investigating the effects of dynamic stretching on balance (6,18,19). They all used a warm-up session before stretching. One of them measured balance before and after the stretching protocol (6), which is similar to our methodology, whereas the others measured only following stretching. Thus, Morrin and Redding (19) recruited 10 trained female dancers and compared the acute effects of dynamic stretching (1x60”), static stretching (2x30”), non-stretching (8 min rest after warm-up), and combined (static & dynamic) protocols on static balance. They used a ballet-specific warm-up session before interventions and tested balance only after the interventions. They reported that non-stretching, static stretching, and dynamic stretching did not have significant superiority to each other, consistent with our findings.

Chatzopoulos et al. (18), with the participation of 31 female high school athletes, compared the acute effects of dynamic stretching, static stretching (1x30”), and non-stretching (7 min rest after warm-up) on dynamic balance. They stated that dynamic stretching and no stretching protocols have superiority to static stretching. No explanation of this inconsistency with our findings can be done, as they used a shorter time static stretching than ours. Belkhiria et al. (6) compared the acute effects of three different volumes (4x15”, 8x15” and 12x15”) of dynamic stretching and static stretching on single foot dynamic balance on 28 healthy trained athletes. They found small improvements in star excursion balance test (SEBT) performance with warm-up alone, and stated that there was no substantial effect of adding dynamic or static stretching. Although they remarked that SEBT, which is used to evaluate dynamic balance, may not be the most predictive or appropriate balance test, their findings are compatible with our results.

Two relatively recent reviews discussed the appropriate static stretching duration for optimum performance (1,17). Kay et al. (1) concluded that static stretches totaling shorter than 45" do not decrease power, strength and speed performance. A total of 45° of static stretch for each muscle in the present study affected dynamic balance performance of recreational athletes positively.

Behm and Chaouachi’s (17) conclusion was different, as they indicated that static stretching for each individual muscle should be less than 30° in duration, especially for highly trained athletes.

The present study has revealed that there is no difference between genders, concerning the effect of different stretching exercises on dynamic balance performance, which diverges from the gender difference speculations of Costa et al. (12), who examined only females. Although in the unique study investigating the effect of gender on balance (7) it was hypothesized that stretching may have different effects on balance among genders, as there are gender-based viscoelastic property differences in tendon structures (29) and muscle architecture (30), they found no significant effect of gender on balance, consistent with our findings.

Another important result of this study is that statistically significant improvements of dynamic balance scores in the control group (solely warm-up) were determined. There were no significant changes in Costa et al. (12) study’s control group, whereas Behm et al. (2)’s results were similar to ours in this instance. This can be explained with warm-up exercises that increase nerve conduction speed (31,32), and thus the speed of response, which is considered to be perturbed balance (2). McHugh and Cosgrave
Dynamic or static stretching after warm-up and solely warm-up positively affect dynamic balance performance, with no significant superiority to each other in this respect. Consideration of stretching protocols without warm-up seems to be a better strategy in future research focusing on the acute effects of stretching exercises on dynamic balance performance.
